BIOLOGICAL CONTROL OF SOIL-BORNE
PLANT PATHOGENS BY TRICHODERMA HARZIANUM

Abstract

Trichoderma harzianum antagonistic to Sclerotium rolfsii and Rhizoctonia solani was isolated from soil. No antibiotic activity of T. harzianum towards the pathogens could be detected. When grown on the pathogen's cell walls, the fungus produced extracellular β-(1,3)-glucanase and chitinase. When applied in the form of wheat bran culture to soil infested with Rh. solani or S. rolfsii in the greenhouse, T. harzianum effectively controlled damping-off disease of bean, peanuts and eggplants caused by these soil-borne plant pathogens. Field experiments were carried out and a significant reduction in disease incidence was obtained. Application of PCNB at subinhibitory doses improved control of disease when applied together with the Trichoderma preparation.

Introduction

In recent years the increasing use of potentially hazardous fungicides in agriculture has been the subject of growing concern of both environmentalists and public health authorities. The possibility of controlling plant-pathogenic fungi by antagonistic micro-organisms added either as a substitute or as an additive to fungicides has been the subject of extensive research. Among the many potentially antagonistic soil inhabitants, members of the genus Trichoderma have gained considerable success (Dennis and Webster, 1971).

Recently, Hadar et al. (1975) found an isolate of T. harzianum which directly attacked the mycelium of Rhizoctonia solani. When applied to soil artificially infested with Rh. solani, a wheat-bran culture of the antagonist effectively controlled damping-off of bean, tomato and eggplant seedlings in the greenhouse. This isolate, however, was not effective against Sclerotium rolfsii, neither
in culture nor in the greenhouse.

In the present study the isolation from soil of another strain of T. harzianum capable of decreasing incidence of various plant diseases caused by both Rh. solani and S. rolfsii in naturally infested soil in the greenhouse and the field, is reported.

Material and methods

Fungi isolated from soil were tested for their antagonistic ability towards soil-borne pathogens as described by Dennis and Webster (1971), using the solidified synthetic medium (SM) of Okon et al. (1973). The isolate used in this work was identified as Trichoderma harzianum Rifai according to Rifai (1969).

Greenhouse experiments

A loamy sand soil (Hadar et al., 1978), artificially infested with either Rh. solani or S. rolfsii, was used. Rh. solani was grown as a thin mycelial mat on yeast extract-dextrose broth (Henis and Ben-Yephet, 1970) for 8 days at 27°C. Then the mycelial mat was washed with sterile water, blotted between two sheets of filter paper, taken in 100 ml water and homogenized in a Waring Blender for 60 sec. It was mixed with the soil at a final concentration of 250 mg wet weight/kg soil. S. rolfsii was grown on SM agar for 10 days. Sclerotia were harvested and mixed with the soil at a final concentration of 100 mg (fresh weight)/kg soil (dry weight).

The antagonistic isolate of T. harzianum was grown on a wheat-bran tap water (1:2) mixture which was autoclaved for 1 h at 121°C twice in two successive days. Erlenmeyer flasks (250 ml) containing this medium were inoculated with T. harzianum and incubated in the dark for 8 days at 30°C. On the third day, cultures were exposed to fluorescent light for 12 h. This culture was mixed with the infested soil at various levels. The soil was distributed in plastic boxes (9 x 9 x 10 cm) containing 500 g soil, and nine seeds of bean (Phaseolus vulgaris L.) were planted in each box. Disease was recorded 21 days after inoculation. Eggplant (Solanum melongena L.) seedlings (one day after emergence) were planted into infested soil (nine seedlings/box). Disease was recorded until damping-off ceased. Plants were grown under greenhouse conditions at 24-30°C. Disease incidence was expressed either as percentage of diseased seedlings or as disease index (Sneh et al., 1966). All treatments were done in six replicates. Experiments were repeated at least twice.

Field experiments

Peanut (Arachis hypogaea L.) was sown under field conditions, in naturally infested alluvial soil. This experi-
ment consisted of a randomized block design and was carried out in five replicates. The plants were grown during the summer and irrigated every two weeks with a total amount of 75 mm water/100 dm².

Results and discussion

Utilization of carbon sources by Trichoderma harzianum

In contrast to the isolate used in a previous work (Hadar et al., 1978), which attacked only R. solani, this isolate of Trichoderma was capable of degrading cell walls of both R. solani and S. rolfsii. All compounds tested known to be components of fungal cell walls (Bartnicki-Garcia, 1973) could be utilized by T. harzianum (Table 1).

Of these, laminarin (β-1,3-glucan) was found most suitable for growth. Indeed, in a previous study, it was found that T. harzianum released highly active β-(1,3)-glucanase and chitinase into the growth medium (Hadar et al., 1978).

Greenhouse experiments with artificially infested soil

When the wheat bran preparation was applied to various soils artificially infested with R. solani and planted with eggplant seedlings, a pronounced reduction of about 50% in disease incidence was observed (Table 2).

A positive correlation between the amount of Trichoderma preparation and disease reduction was observed in all experiments. Similar results were also obtained with S. rolfsii in bean seedlings (see Figure 1). A high disease incidence was observed 17 days after sowing when plants were grown in the non-treated soil, while at both concentrations of the Trichoderma preparation used, a significant

* Within each line, values followed by a common letter are not significantly different \( P = 0.05 \) using Duncan's multiple range test. A significant reduction in disease incidence was observed.

Fig. 1 Development of damping-off incidence in bean seedlings in soil infested with Sclerotium rolfsii (●) compared with seedlings in infested soil amended with Trichoderma preparation: ○ - 1.0 g/kg; △ - 3 g/kg. Treatments were significantly different \( P = 0.05 \) from the control from the 14th day, using Duncan's multiple range test.

Greenhouse experiments with naturally infested soil

The same Trichoderma preparation was also used in a soil naturally infested with both Rh. solani and S. rolfsii, using bean seedlings as test plants. Again, a significant control was achieved with both diseases (Table 3).

$^y$ Within each column, values followed by the same letter are not significantly different ($p = 0.05$) using Duncan's multiple range test.

Combined biological and chemical control

An integrated control of Sclerotium rolfsii was tried by using a combination of T. harzianum preparation and the fungicide pentachloronitrobenzene (PCNB) at low dosages. The results (Table 4) indicate a synergistic interaction between both treatments since the control achieved in the combined treatment was greater than the sum of the different treatments.

</tr>
</tbody>
</table>

$^x$ Values followed by a common letter are not significantly different ($P = 0.05$) using Duncan's multiple range test.

These results indicate that integrated control of soil-borne pathogens is possible, thus minimizing soil pollution and interference in biological balance (Papavizas, 1973; Baker and Cook, 1974; Henis and Chet, 1975).
Field experiment

The results obtained under greenhouse conditions encouraged us to test the efficiency of the Trichoderma preparation under field conditions. The wheat-bran preparation of *T. harzianum* was applied along with peanut seeds at a concentration of 15 g preparation/m². The results are summarized in Table 5.

**TABLE 5**

Biological control of *S. rolfsii* in peanut plants in a naturally infested field soil

</tr>
</tbody>
</table>

Within each column, values followed by the same letter are not significantly different (P = 0.05) using Duncan’s multiple range test.

From the data obtained under greenhouse and field conditions it appears that *T. harzianum* preparation is effective in controlling *S. rolfsii* and *Rh. solani* in both artificially and naturally infested soil.

These results are similar to those reported by Wells et al. (1972) and Backman and Rodri uez-Kabana (1975) using for biological control ryegrass and molasses as a food base for *T. harzianum*, respectively, whereas we have followed Hadar et al. (1978) using wheat-bran.

However, whereas in the former study (Hadar et al., 1978) we have reported on an isolate which attacks only *Rh. solani* under greenhouse conditions, the isolate of *T. harzianum* used in the present study is capable of controlling both *Rh. solani* and *S. rolfsii*. The biochemical basis of this difference in specificity is not known yet and is under investigation.
